Biological Sciences Division and Environmental Molecular Sciences Laboratory, Pacific Northwest National Laboratory, Richland, Washington 99352

Ion mobility spectrometry (IMS) coupled to orthogonal time-of-flight mass spectrometry (TOF) has shown significant promise for the characterization of complex biological mixtures. The enormous complexity of biological samples (e.g., from proteomics) and the need for both biological and technical analysis replicates imposes major challenges for multidimensional separation platforms with regard to both sensitivity and sample throughput. A major potential attraction of the IMS-TOF MS platform is separation speeds exceeding that of conventional condensed-phase separations by orders of magnitude. Known limitations of the IMS-TOF MS platforms that presently mitigate this attraction include the need for extensive signal averaging due to factors that include significant ion losses in the IMS-TOF interface and an ion utilization efficiency of less than ~1% with continuous ion sources (e.g., ESI). We have developed a new multiplexed ESI-IMS-TOF mass spectrometer that enables lossless ion transmission through the IMS-TOF as well as a utilization efficiency of >50% for ions from the ESI source. Initial results with a mixture of peptides show a ~10-fold increase in signal-to-noise ratio with the multiplexed approach compared to a signal averaging approach, with no reduction in either IMS or TOF MS resolution.

Since its introduction as an analytical technique in early 1970s,¹ ion mobility spectrometry (IMS) has been increasingly applied to the characterization of gas-phase ions in a number of applications, including quality control in semiconductor manufacturing processes,² environmental monitoring of air and water,³ detection of explosives,⁴ and chemical warfare agents and toxins.^{5,6} IMS is based on spatial separation of gas-phase ion species due to differences in their mobilities through a buffer gas, analogous to capillary electrophoresis (CE) in the condensed phase.

Coupling of electrospray ionization (ESI) and matrix-assisted laser desorption/ionization to IMS has provided an impetus for expanding the realm of IMS capabilities to proteomics and other

system biology applications.^{7,8} The enormous complexity of biological systems, (e.g., >20 000 different proteins may be expressed at detectable levels by a mammalian system⁹) has challenged the separation and analysis power of existing approaches and to this point has been most effectively addressed by combinations of orthogonal fractionation and separation techniques combined with mass spectrometry (MS) as a final separation stage due to its high sensitivity, resolution, broad dynamic range, and accurate mass measurement capability. Protein detection and identification in a variety of important biomedical applications, including discovery of candidate biomarkers in human blood plasma for early cancer detection, represents a significant analytical challenge for condensed-phase multidimensional separations coupled to MS, as many proteins of interest are expected at abundance levels far below that of higher abundance proteins.¹⁰ The large dynamic range of interest (>10¹⁰), coupled with issues that derive from biological variation, has greatly hindered proteomic approaches for effectively discovering low-level candidate biomarkers in such biological fluids. Liquid chromatography (LC)–MS-based proteome analysis of human blood plasma has generally involved the coupling of a high-abundance protein depletion step with intensive protein- or peptide-level fractionation/separation techniques to obtain a greater analytical “depth of coverage”. This approach effectively transforms each sample into many samples and thus reduces the number of individual samples that can be analyzed. At present, for example, it is not practical to perform in-depth proteomic studies involving several hundred individual human blood plasma samples. This throughput versus proteome analysis coverage tradeoff can be addressed by either increasing the depth of coverage in a single analysis or the throughput of current approaches. Since gas-phase ion separations are typically 2–3 orders of magnitude faster (~10–100 ms) than fast reversed-phase (RP) LC separations of comparable separation power (~5–10 min), IMS represents an attractive complementary orthogonal separation approach. When introduced between the condensed-phase separation and MS analysis, IMS can potentially increase the total effective peak capacity of a fast RPLC–MS platform by over 1 order of magnitude without affecting the overall analysis

speed and, thus, help in addressing both the depth of coverage and throughput needs.

IMS, in turn, benefits from coupling with fast MS detection capable of acquiring the entire mass spectrum in a single scan. Young et al. first coupled a lower pressure IMS to an orthogonal time-of-flight (TOF) analyzer to measure the formation and decomposition rates of hydrates of hydronium ion.¹¹ More recently, this approach was used in combination with ESI for characterization of different biochemical compounds.^{12,13} Despite its attractiveness for higher throughput proteomic studies, the application of IMS-MS has been limited by low sensitivity primarily arising from ion losses at the IMS-MS interface and low duty cycle. Tang et al. have recently reported on ion lossless IMS-MS separations with an IMS drift tube incorporated between two electrodynamic ion funnels.¹⁴ In that experiment, ions were trapped in an "hourglass" ion funnel for 50–100 ms at an elevated pressure of 4 Torr and then gated into the IMS drift tube in short 50- μ s pulses. At the exit of the IMS drift tube, ion packets, spatially dispersed mainly due to thermal diffusion,¹⁵ were captured by a regular ion funnel followed by a short collisional quadrupole. These developments have also recently been adopted by Clemmer and co-workers.¹⁶ Though ion transmission drastically improved as compared to earlier implementations of IMS-oTOF design,¹⁷ we also note that lower efficiency of ion trapping/accumulation in the ion funnel still limits the ion utilization efficiency or duty cycle.

The duty cycle of IMS with a continuous ion source can be improved using a Fourier transform approach.^{18,19} Using two gates at the entrance and at the exit of the drift region allows the "front" and "exit" gate opening and closing voltages to be correlated with the drift time for ions of interest. This approach provided a 3–5-fold increase in the signal-to-noise ratio (SNR) for the ions of a specific drift time at any given moment. Obtaining improved sensitivity for *all* species in a single IMS separation requires a multiplexing technique, such as the Hadamard transform (HT). HT has been extensively used in optical spectrometry for over five decades.²⁰ The concept of measuring different bundles of objects by weighing them in groups rather than individually was first proposed by Fellgett, and the resulting increase in accuracy is sometimes called the Fellgett or multiplex advantage.^{21,22} If spectral line intensities are simultaneously detected in N measurements, the theoretical increase in SNR over a single measurement

is then expected to be $\sim(N)^{1/2}$. Decker has experimentally demonstrated such an SNR gain by comparing the mercury vapor emission spectra obtained with both a monochromator and a Hadamard transform spectrometer.²³ HT has been successfully applied to TOF MS and CE, yielding an increase in the duty cycle up to 50%. In CE experiments with fluorescence detection, Kaneta et al.²⁴ have experimentally demonstrated an SNR increase by a factor of 8, which was in excellent agreement with the theoretically predicated value of 8.02. CE multiplexing was achieved by photodegradation of a light-absorbing analyte, an approach that would be difficult to implement with a complex biological sample. For an HT on-axis TOF MS, a proof-of-principle has been demonstrated using both direct infusion²⁵ and CE,²⁶ although no comparison with conventional signal averaging was reported. A 5–6-fold increase in sensitivity has recently been reported in HT measurements using atmospheric-pressure IMS separations (without MS).^{27,28} This improvement, however, falls short of the theoretically expected gain of 15–45 (the theoretical gain for a 13-bit sequence is $(2^{13} - 1)^{1/2}/(2) \cong 45.25$). The discrepancy can be explained, in part, by the fact that the encoding pseudorandom binary sequence used in these multiplexing experiments exceeded the ion mobility drift times by almost 2 orders of magnitude. As a result, only a small fraction of the sequence contributed to any SNR enhancement as compared to that of a conventional averaging approach.

Here we describe the first implementation of ESI-multiplexed ion mobility spectrometry combined with orthogonal TOF mass spectrometry. The high transmission efficiency, increased sensitivity, high throughput, and resolving power achievable provide a basis for the development of an advanced proteomics platform.

EXPERIMENTAL SECTION

The multiplexed IMS-TOF MS approach has been implemented using two commercial orthogonal TOF instruments: a Q-Star Pulsar (Sciex, Toronto, Canada) and an Agilent TOF (Agilent, Santa Clara, CA) (Figure 1). The design of an ESI source and IMS drift tube coupled to both TOF spectrometers has been described elsewhere.¹⁴ The ESI source incorporated a 50- μ m-i.d. fused-silica tip electrospraying into a 64 mm-long, 430- μ m i.d. heated inlet capillary operating at a temperature of ~ 120 °C. The ESI emitter was mounted on a 2D translation stage enabling fine position adjustment with respect to the inlet. All voltages in the ESI source were referenced to a 4-kV potential applied to the IMS drift tube.

Following droplet desolvation in the inlet capillary, intact ions were introduced into an hourglass ion funnel at 4 Torr for further trapping and accumulation. The hourglass ion funnel consisted of 0.5-mm-thick, 100 ring electrodes, separated by 0.5-mm-thick Teflon spacers. The front section of the funnel incorporated a tapered converging assembly of 42 electrodes whose diameter was linearly decreasing from 25.4 to 2 mm. The exit diverging section of the hourglass ion funnel encompassed a set of 10

Figure 1. Schematic of the ESI multiplexed IMS-TOF MS instrumentation. The IMS gate is modulated using a pseudorandom binary sequence. Gate open events are synchronized with TOF extraction pulses, resulting in <1-ns timing jitter. The inset schematically shows ion dispersion in the IMS instrument. Indexes k and j correspond to the modulation bin number and the elapsed time, respectively.

electrodes of 25.4 mm in diameter (20 mm in diameter for the funnel coupled to Agilent TOF), with a 20 lines/in. mesh (Buckbee-Mears, St. Paul, MN) mounted on the exit funnel plate. The first and the last-but-one electrodes of the straight exit section of ion funnel were independently driven at a potential of 40 V, while the potential at the exit electrode was switched between 60 and 28 V, enabling ion accumulation and gating into the IMS drift tube, respectively. Ion packet multiplexing was conducted by encoding the gating potential (i.e., a potential applied to the funnel exit electrode) with a pseudorandom binary sequence (PRS). Switching potentials on the ion funnel floating at 4-kV potential was implemented with a fiber-optic triggering circuitry. Similar to the conventional ion funnel,²⁹ an alternating rf potential at a frequency of 500 kHz and a peak-to-peak amplitude of 90 V was applied to all funnel plates except for the last dc-only plate, and a dc gradient of 24 V/cm was produced to assist ion transmission in the axial direction.

An IMS drift tube, coupled to the TOF Q-Star Pulsar, consisted of 55-mm-i.d., 80-mm-o.d. 210 copper electrodes separated by 10-mm-long tubular plastic spacers, establishing a 2100-mm-long separation region. Pressure in the drift region was ~4 Torr (N_2), and the electric field strength was ~2 kV/m. An 840-mm-long IMS drift tube interfaced to Agilent TOF was operated under 2.8 Torr pressure (N_2) and electric field strength identical to that used in the IMS-Q-Star instrument.

To capture all ions exiting the IMS separation region, an additional 100-mm-long ion funnel was employed. This funnel was driven at the same rf and dc fields as the front-end hourglass funnel and then coupled to a 25-mm-long collisional quadrupole operating at a frequency of 2 MHz and a peak-to-peak amplitude of 200 V. The quadrupole manifold was evacuated by a mechanical pump (Alcatel 2033, 12.8 L/s) to provide a pressure drop to ~140 mTorr and an interface for the IMS drift region to the lower pressure rf ion guides of the commercial TOF instruments.

Both the Q-Star Pulsar and Agilent TOF were coupled to a 10-GHz time-to-digital converter (Ortec 9353, Oak Ridge, TN). Timing sequences were set by an I/O control board PCI-6711 (National Instruments, Austin, TX) installed in a Dell PC running on Windows XP operating system. Data acquisition software was developed in-house using Visual C# and implemented on top of the Active X controls running Ortec hardware. To synchronize IMS and MS operations, the IMS pulsing period was made divisible by the TOF acquisition period and user-defined from the data acquisition software. Once the desired sequence for multiplexing was programmatically generated, the PRS was uploaded to PCI-6711 that was triggered by a TOF extraction pulse. In this approach, an electronic jitter of <1 ns was achieved between the onset of TOF spectrum acquisition and triggering signal employed for opening or closing an IMS gate. The IMS gate opening time in both standard and multiplexed experiments was 100 μ s. A typical IMS separation and TOF scan durations were 127 ms and 100 μ s, respectively. Each TOF mass spectrum acquisition was digitized at 1.6-ns resolution (i.e., $2^N \times 0.1$ ns, where $N = 4$), yielding 62 500 TOF bins per TOF scan and $\sim 8 \times 10^7$ bins per single IMS separation.

Peptides used in this study were purchased from Sigma Aldrich (St. Louis, MO) and further analyzed without additional purification. Samples diluted in water/methanol/acetic acid buffer (79.64: 20:0.36 v%) were introduced into the instrument at a flow rate of 0.4 μ L/min by a syringe pump (KD Scientific, Holliston, MA).

RESULTS AND DISCUSSION

Modeling. We extensively modeled the reconstruction of signals generated in the multiplexed IMS-TOF MS approach using Microsoft Visual C++, and only a small portion of that work is presented here. Modeling was performed by assuming that (i) ion packet broadening in the IMS drift tube is mainly driven by thermal diffusion, facilitating independent ion packet dispersion, and (ii) the spatial distribution of an ion cloud is governed by the central limit theorem, resulting in a Gaussian ion density profile along the IMS drift axis. Although space charge effects contribute to the overall expansion of an ion cloud in the IMS drift tube,³⁰ the estimations indicated they contributed <5% of that exerted by the thermal diffusion under our experimental conditions, which account for ~1 nA pulsed ion current resulting from ion accumulation in the funnel.

Ion motion in the IMS drift tube is determined by the ion mobility constant, K , whose equation was derived by Revercomb and Mason:³¹

$$K = \frac{3}{16} \frac{Ze}{N} \sqrt{\frac{2\pi}{kT} \left(\frac{1}{m} + \frac{1}{M} \right)} \frac{1}{\Omega_0} \quad (1)$$

where Ze is the ion charge, N is the number density of the gas, m and M are the masses of the drift gas and analyte, respectively, k is Boltzmann's constant, T is the absolute temperature of the drift gas, and Ω_0 is the diffusion collision integral. The drift velocity, v_d , in the lower electric field of intensity E is determined by the field-independent ion mobility constant, K , as follows:

$$v_d = KE \quad (2)$$

(29) Belov, M. E.; Gorshkov, M. V.; Udseth, H. R.; Anderson, G. A.; Smith, R. D. *Anal. Chem.* **2000**, *72*, 2271–2279.

We first consider identical ion species whose gating into the IMS drift tube is determined by a PRS. Since ion packets disperse along the drift axis independently of each other, the temporal, $\Delta t_{j,k}$, and spatial spread, $\Delta x_{j,k}$, of an ion packet within the IMS drift tube can be estimated as

$$\Delta t_{j,k} = \sqrt{t_g^2 + (t_{j,k}/R_d)^2} \quad (3)$$

$$\Delta x_{j,k} = v_d \Delta t_{j,k} \quad (4)$$

$$t_{j,k} = t_{\text{TOF}} \times j - t_{\text{offset}_k} \quad (5)$$

$$t_{\text{offset}_k} = t_{\text{TOF}} \times k \times \text{PRS}_k \quad (6)$$

$$R_d = \sqrt{\frac{ZeEL_d}{kT \ln 2}} \quad (7)$$

$$x_{j,k} = v_d t_{j,k} \quad (8)$$

where j is the temporal step index, k is the modulation bin index within PRS, PRS_k is the digital “1” or “0” event, which represents an “on” or “off” gate status, $t_{\text{TOF}} \times j$ is the elapsed time synchronized with the PRS onset, t_{offset_k} is the temporal offset of the ion packet gated into the IMS drift tube in k th modulation bin relative to the PRS onset, $t_{j,k}$ is the drift time of the ion packet gated into the IMS drift tube in k th modulation bin, t_g is the gate opening time, t_{TOF} is the spectrum acquisition rate with a TOF mass spectrometer, $x_{j,k}$ position of the center of k th ion packet at time t_j , R_d is the diffusion-only resolving power,³¹ and L_d is the length of the IMS drift tube. In multiplexing approach, ion packet gating into the IMS drift tube occurs at different times during the IMS separation, and gating events are delayed relative to the PRS onset. Equations 3–5 and 8 determine the temporal spread, spatial spread, drift time, and drift distance of an ion packet gated into the IMS drift tube in k th modulation bin, respectively. Index j indicates that the measurements of the above metrics are performed at a time instant of $t_{\text{TOF}} \times j$. Index k corresponds to the modulation bin number and accounts for the delay between the PRS onset and gating event (eq 6). Equation 3 is similar to that reported previously,^{31,32} except for the dependence of the drift time on the modulation bin number, a difference that can be better understood by examining a snapshot of IMS separation at the end of the encoding sequence. In this case, an ion packet launched into the IMS drift tube by the first “gate on” event would approach the end of the drift region and exhibit the full dispersion due to thermal diffusion, while the temporal spread of an ion packet gated into the drift region just before taking the snapshot would be characterized only by the gate opening time, t_g . At a given elapsed time, the spatial distribution of ions within different ion packets would depend on ion packet position along the drift tube. The inset in Figure 1 schematically shows ion packet dispersion in the IMS drift tube. For the three ion packets illustrated, the area under the curve is conserved, representing the number of ions injected into the IMS instrument during constant gate opening intervals, while the positions of the maximums and the spatial distributions are determined by eqs 3–8.

The number of ions as a function of their position along the IMS drift tube can be then evaluated as

$$N_{\text{ions_IMS}_{i,j,k}} = \frac{N_{i+1,j,k} - N_{i,j,k}}{2} \quad (9)$$

$$N_{i,j,k} = N_0 \int_{x_{j,k}-\text{step} \times i}^{x_{j,k}+\text{step} \times i} \frac{1}{\sqrt{2\pi}\Delta x_{j,k}} \exp\left(-\frac{(x-x_{j,k})^2}{2\left(\frac{\Delta x_{j,k}}{2}\right)^2}\right) dx \quad (10)$$

where i is the spatial step index, step is the spatial step, N_0 is the total number of ions in a given packet, $N_{i,j,k}$ is the number of ions within a spatial interval of $[x_{j,k} - \text{step} \times i; x_{j,k} + \text{step} \times i]$, and $N_{\text{ions_IMS}_{i,j,k}}$ is the number of ions within a spatial interval of $[x_{j,k} + \text{step} \times i; x_{j,k} + \text{step} \times (i+1)]$ along the IMS drift tube. Note, that N_0 is considered to be a time-independent constant that is a first-order approximation for a relatively stable continuous ion source, such as from ESI. A three-dimensional integral, $N_{\text{ions_IMS}_{i,j,k}}$, interpolated with Chebyshev's polynomials in the software, defines the spatial distribution of all ion packets along the IMS drift axis at any given time.

To convert the spatial distribution of ions in the IMS drift tube to the number of ions to be extracted into the orthogonal TOF MS flight tube, ion signals from all the ion packets in the IMS drift tube that contribute to the ion distribution inside the TOF extraction region were summed for each TOF mass spectrum acquisition. Importantly, since the PRS is synchronized with a TOF pulser (see eqs 5 and 6), each summation corresponded to the number of ions that were gated into the TOF flight tube. Modeling also allowed for the oversampling of the modulation bins, so that a modulation bin width could be a multiple of several TOF acquisitions. Given an ion's mass-to-charge ratio, $(m/z)_n$, and a calibration coefficient, slope, a TOF function, TOF_n

$$\text{TOF}_n = \frac{\sqrt{(m/z)_n}}{\text{slope}} \quad (11)$$

was then added to the total IMS drift time and the ion arrival time at the detector was obtained.

Typical parameters used for ion mobility modeling included an IMS drift tube length of 2 m, an IMS drift tube pressure of 4 Torr, and an electric field strength in the IMS drift region of 2 kV/m, corresponding to 4-kV potential applied to the first IMS electrode. TOF parameters in the reflectron mode were chosen such that m/z 500 would arrive at the TOF detector in 50 μs following the extraction pulse. The length of the TOF extraction region (where signals from all ion packets encoded by the PRS were summed) was 30 mm. The encoding 9-bit sequence comprised 511 modulation bins that were each 200 μs long, giving rise to an IMS separation time of ~ 100 ms. Each modulation bin was synchronized with a 100- μs -long TOF mass spectrum acquisition that, in turn, incorporated 10^3 TOF detector bins. The TOF detector bin width of 100 ns was limited only by a PC SDRAM and was considered to be adequate for multiplexed IMS-TOF modeling. Given the TOF acquisition rate, signal reconstruction was performed at an oversampling rate of $>10^3$. The principle of signal reconstruction using inverse transform with a generalized

inverse matrix under the conditions of major oversampling ($>10^5$) has been reported elsewhere³³ and successfully implemented in experiments using multiplexed orthogonal TOF.³⁴ In general, given an inverse matrix of $N \times N$ elements, S^{-1} , and a detected signal vector of M elements, y , where M is a multiple of N and $M \gg N$, the latter is split into N bins to enable deconvolution of the original M -element signal vector, z , in M/N inverse transforms.

$$z = S^{-1} \cdot y \quad (12)$$

The details of the multilayer signal reconstruction where a modulation bin comprises multiple TOF mass spectra that, in turn, encompass a large number of TOF bins are given in the Supporting Information. Importantly, the compression of the experimental multiplexed IMS-TOF signal (i.e., removal of zero entries from TOF spectra) yielded a fully reconstructed 2D separation in less than 1 min, an attractive feature, for example,

for on-line LC fractionation coupled to a multiplexed IMS-TOF MS instrument.

Figure 2A shows the modeled raw signal obtained with an equimolar mixture of six peptides. To generate this signal, 100 ions for each peptide were introduced into the IMS drift tube during each 200- μ s-long “gate open” event in a 9-bit modulation sequence. The modeling assumed ideal ion transmission; i.e. all ions gated into the IMS region reach the MS detector. A significant intermingling of ion packets is observed in the IMS drift tube. An inset to Figure 2A shows the MS signal from a portion of the IMS separation corresponding to one TOF mass spectrum. Figure 2B shows an IMS-TOF MS signal reconstructed by inverse transformation of a 511×511 simplex matrix. A characteristic feature of this reconstruction is the mathematical pseudonoise observed at the background level, as shown in the inset. Similar background noise has been observed in HT-TOF MS measurements, and Poissonian statistics for the arrival times of ions at the detector have been employed to estimate the magnitude of the baseline noise as a function of mass spectral features and acquisition conditions.³⁵ The magnitude of the pseudonoise was

(33) Belov, M. E.; Fancher, C. A.; Foley, P. U.S. Patent 6,900,431, 2005.

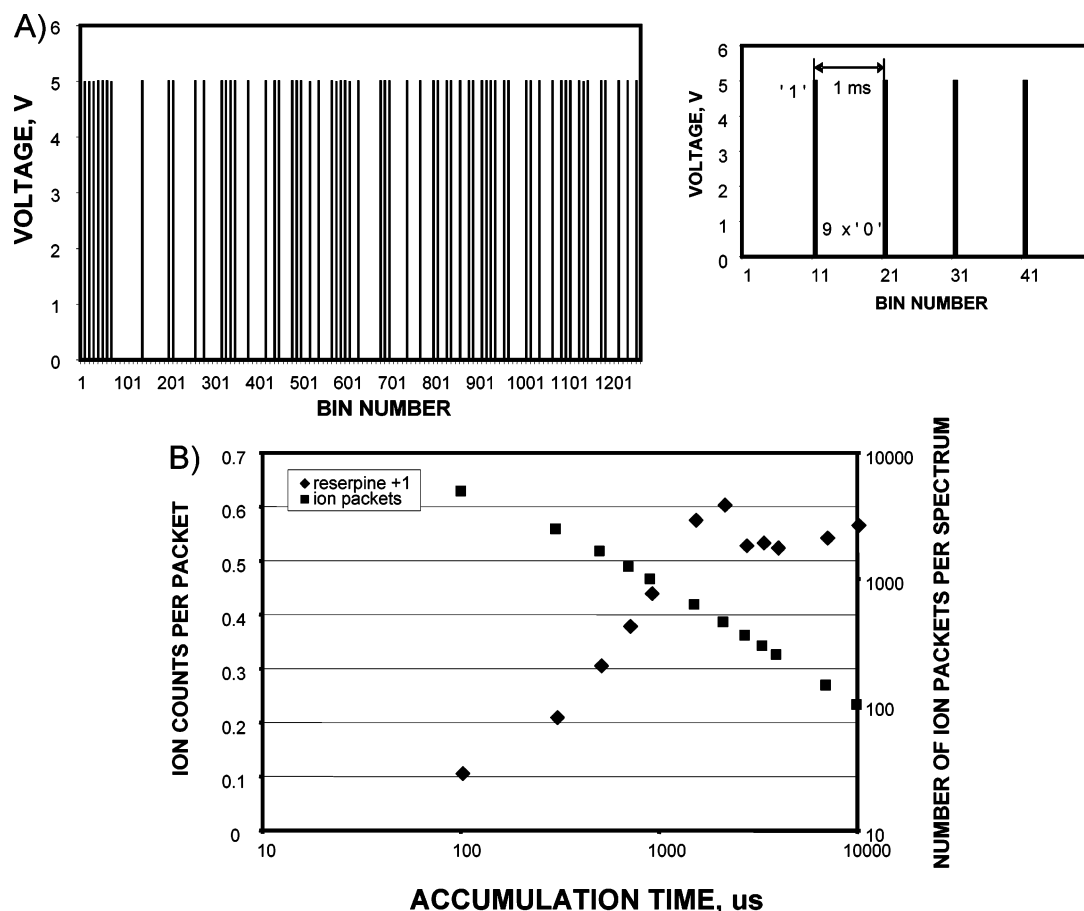

Figure 3. (A) Experimental extended 7-bit maximum length pseudorandom sequence. Each pulse corresponds to the ion gating into the IMS drift tube. Inset shows a portion of the sequence. The gating pulse duration was 100 μ s. The shortest interval between the gating pulses was 900 μ s and the longest was 6900 μ s. To perform signal reconstruction, the extended 1270-element sequence was folded into a 127-element weighed vector, with each element obtained by summing 10 preceding elements. (B) Dependence of the 1 μ M reserpine signal per single TOF scan on the ion accumulation time in the hourglass ion funnel. Data were acquired with IMS-TOF (Q-Star Pulsar) MS operated in the signal averaging mode.

found to be dependent on the temporal separation between two adjacent packets and represents the overlapping of spatial distributions of ion packets launched in different modulation bins. In an extreme case, ion packet broadening due to thermal diffusion results in a significant increase in the pseudonoise, making multiplexing impractical. Therefore, thermal diffusion imposes a fundamental limitation on the encoding sequence length (i.e., the number of bins in a sequence) and sets the minimum interval desirable between two adjacent gate pulses. On the other hand, the sequence length must not exceed the time scale of an IMS separation in the standard averaging mode, as no SNR improvement can be gained on the time scale longer than that of a single signal averaging experiment. To better understand the last statement, one can compare signal averaging against multiplexing, where two acquisitions in the multiplexed mode are performed on a time scale of one acquisition in signal averaging mode. The SNR improvement obtained using the multiplexed approach is $2^{1/2}$ compared to signal averaging; four acquisitions in the multiplexed mode provide a factor of 2 gain, while signal averaging would result in $2^{1/2}$ gain. The obtainable gain thus depends on the

number of multiplexed acquisitions made on the time scale of a single signal averaging experiment; the advantage of multiplexing is that one can perform multiple acquisitions in the multiplexed mode on the time scale of the signal averaging experiment. In the above example, the signal averaging approach would provide the same SNR if performed on a time scale two times longer than that of the multiplexed experiment. Multiplexing provides the basis (due to the encoding–decoding algorithm) for more acquisitions on the time scale of a single signal averaging experiment, and the benefits of multiplexing would only be realized for a portion of the encoding sequence that corresponds to the duration of the IMS separation in signal averaging mode.

Experiment. Our experimental implementation of multiplexed IMS-TOF measurements has been guided by these modeling results and using similar signal reconstruction routines. Figure 3A shows the encoding sequence used for the multiplexed IMS-TOF MS experiments. The important difference between this sequence and the conventional encoding sequences used in HT photospectrometry,²⁰ HT-TOF MS,²⁵ HT-CE,²⁴ and HT-IMS²⁷ is that the adjacent digital “1” events (i.e., “gate open” events) in our sequence are separated by “0” events (i.e., “gate closed” events), while a typical encoding sequence in HT experiments has combinations of consecutive “1” events.

Figure 4. Experimental raw data signal obtained with 1 μM solution of reserpine in multiplexed IMS-TOF MS (Q-Star Pulsar) experiment. Multiplexed IMS-TOF raw signal was acquired at 1.6-ns resolution and summed over 1000 IMS acquisitions, corresponding to 127 s. Inset A shows a small portion of the multiplexed IMS-TOF MS measurement corresponding to 8 mass spectra. Inset B shows a portion of one of the mass spectra in inset B, corresponding to the reserpine peak. The signal maximum obtained in the signal averaging IMS-TOF experiment (dashed line) is compared to the raw (unreconstructed) multiplexed IMS-TOF signal (solid line).

Three objectives were achieved by introducing delays between two adjacent ion releases into the IMS drift tube. First, extending the timing interval between two neighboring ion packets reduced the detrimental effects of diffusion-driven ion dispersion upon signal reconstruction, thus decreasing the mathematical noise upon signal reconstruction. Second, the constant short gate opening time ($\sim 100\ \mu\text{s}$, see inset) minimized peak broadening due to the gating term, t_g , in eq 3. For comparison, in an HT-IMS experiment with a conventional 13-bit PRS²⁷ implemented at a rate of $150\ \mu\text{s}$ per modulation bin, the longest gate open event would be $\sim 2\ \text{ms}$. As a result, the gate opening time would on average exceed that of the signal averaging mode by $\sim 3\text{--}4$ -fold, resulting in peak broadening. Third, ions delivered to the ion funnel from a continuous source can be more efficiently accumulated between two adjacent releases for the shorter periods without exceeding the level at which space charge effects would be problematic and resulting in an increase in the charge density per ion cloud released to the IMS drift tube. To perform signal reconstruction, a 1270-element modulation sequence was folded into a 127-element vector, such that each vector element was a sum of the 10 preceding elements in the modulation sequence. The weighing algorithm is described in detail in the Supporting Information.

As a result, a weighed 127-element PRS was obtained to be used for generation of a generalized weighed matrix and inverse transform.

Since both standard and multiplexed modes incorporated ion accumulation between adjacent gate pulses, the ion signal intensity for one TOF mass spectrum was examined. The interval between two adjacent pulses in the experimental PRS (i.e., ion accumulation intervals), shown in Figure 3A, varied between 1 and 7 ms, while IMS in the signal averaging mode was conducted using one ion packet ejected from the ion accumulation trap every 127 ms. Figure 3B shows the charge density of a trapped ion cloud as a function of the accumulation time in the signal averaging mode. This dependence revealed ion signal saturation from ESI of a $1\ \mu\text{M}$ sample of reserpine for an accumulation time of $\sim 2\ \text{ms}$. Therefore, when comparing the multiplexed versus signal averaging IMS modes of operation, no signal enhancement using the signal averaging IMS mode could be achieved for accumulation events longer than 2 ms with the current design of the ion funnel (presumably due to space charge constraints), and SNR improvement will only be attained via the multiplexing gain or mechanisms other than ion accumulation in the ion funnel trap, e.g., the overlapping of ion packets in the TOF extraction region. Figure

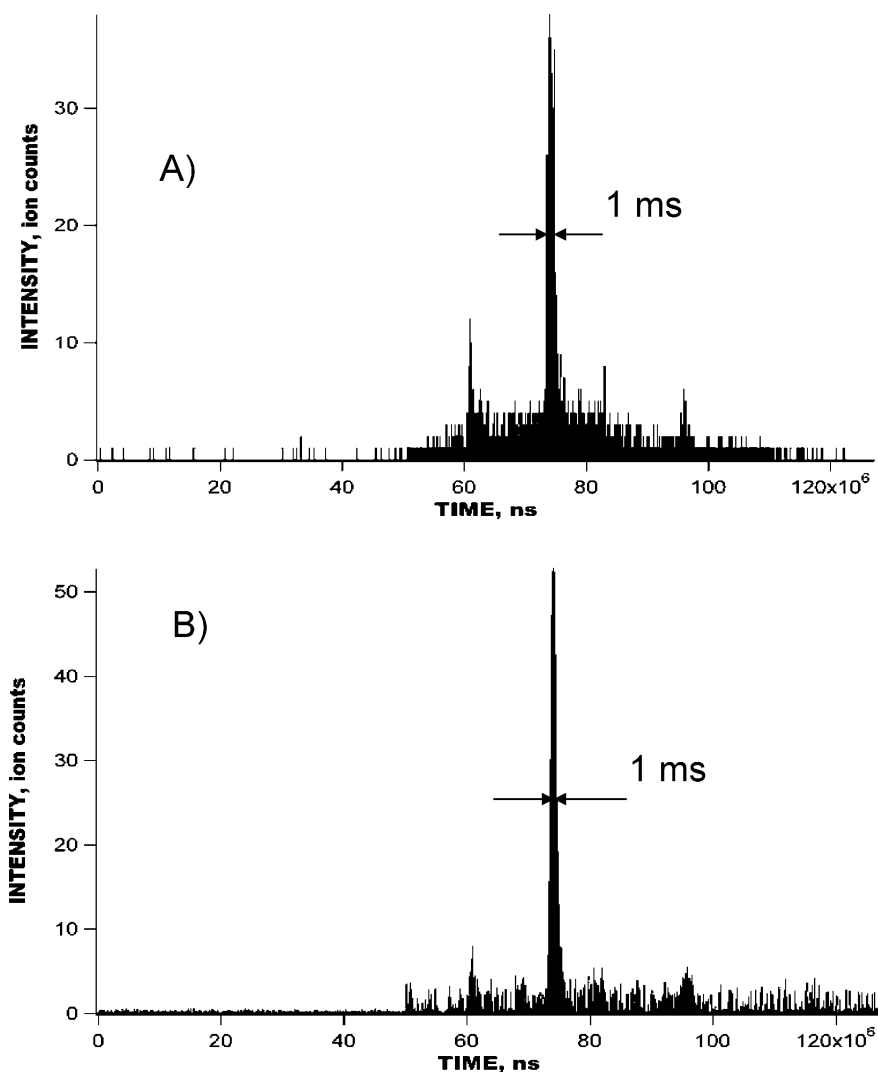

Figure 5. (A) A 1 μ M reserpine signal acquired with the IMS-TOF MS (Q-Star MS Pulsar) instrument operated in the signal averaging mode. Experimental conditions were identical to that in Figure 3A. (B) Reconstructed 1 μ M reserpine signal acquired in the multiplexed experiment with the IMS-TOF MS in Figure 4. Temporal resolution of the reconstructed signal is 1.6 ns. Each IMS separation comprises 1270 TOF scans, and a total of 1000 IMS separations were summed both in the multiplexed and signal averaging modes.

3B also indicates that only a portion of the multiplexed experiment, corresponding to the accumulation intervals of less than 2 ms, could be performed at a duty cycle of $\sim 95\%$. Longer accumulation intervals (>2 ms) within the extended PRS exhibited ion losses similar to those experienced in the signal averaging mode.

Figure 4 shows the raw signal obtained with a 1 μ M reserpine solution using the IMS-TOF Q-Star Pulsar mass spectrometer in the multiplexed mode. IMS-TOF analysis in Figure 4 encompasses 1270 concatenated TOF spectra acquired at a resolution of 1.6 ns, each spectrum being a sum of 1000 TOF mass spectra. The total number of ion packets in the IMS drift tube during a single IMS separation was 64, and each IMS separation was conducted in 127 ms. The inset A shows the detected signal during a small portion of the IMS separation corresponding to eight mass spectra. Since ion packets are encoded in one (IMS) dimension of the 2D separation, the other dimension (MS) can be independently analyzed and compared with the signal averaging approach. The inset B shows a portion of one of the mass spectra generated from the raw (unreconstructed) multiplexed signal in Figure 4 (solid line) in comparison with the maximum observed in a signal

averaging IMS-TOF experiment (dashed line). On average, the signal intensity from the raw multiplexed signal was found to exceed the maximum observed in the signal averaging experiment. Figure 5 shows the comparison between the reconstructed signal acquired in the multiplexed experiment in Figure 4 and that acquired in the signal averaging mode. The IMS-TOF MS was operated under conditions identical to those in Figure 4, so that each IMS separation was performed in 127 ms and comprised 1270 TOF mass spectra. Both multiplexed and signal averaging mode separations were acquired over a period of 127 s, corresponding to 1000 IMS acquisitions. Signal reconstruction in Figure 5B was performed at a resolution of 1.6 ns. The only difference between IMS-TOF separations in Figure 5A,B was the number of ion packets present in the IMS drift tube at a given time. In the experiment conducted in the signal averaging mode (Figure 5A), only one ion packet was injected into the drift tube in the course of the entire 127-ms-long IMS separation, while in the multiplexed experiment, 64 ion packets were present in the IMS drift region at the end of each IMS separation. Two-dimensional signal reconstruction enabled the comparison of the multiplexed and

Figure 6. Portion of the reconstructed multiplexed IMS-TOF separation in Figure 5A (solid line) superimposed with that of IMS-TOF separation conducted in the signal averaging mode in Figure 5B (dashed line). The noise level in the conventional IMS-TOF separation corresponds to single ion counts.

signal averaging experiments in both the IMS and MS dimensions. In the IMS dimension, the reconstructed signal was found to

match that of the conventional IMS for both the drift time and peak width, implying no detrimental effects on the IMS resolving power due to multiplexing. Figure 6 shows a small portion of both the multiplexed (reconstructed) and signal averaging IMS-TOF analyses from Figure 5, representing a small segment of one TOF mass spectrum and showing peaks due to reserpine ions. When compared to the data obtained with the IMS-TOF in signal averaging mode, a ~ 10 -fold SNR increase was observed for the reserpine signal in the multiplexed experiment, exceeding the theoretical multiplexing gain of 5.6 for a sequence of 127 elements (see discussion below). Figure 7 shows the raw multiplexed data obtained with a $1 \mu\text{M}$ mixture of bradykinin, angiotensin I, fibrinopeptide, and neurotensin in the multiplexed experiments using an IMS-Agilent TOF MS instrument. Since multiple species with different mobilities are gated into the IMS, ions from different ion packets are intermingled in the TOF extraction region, representing a challenge for signal reconstruction. The insets A and B show portions of the IMS separation corresponding to single TOF spectra. Signal acquisition parameters, including TOF scan and IMS separation durations, TOF digitization rate, and the number of IMS acquisitions were the same as for the multiplexed

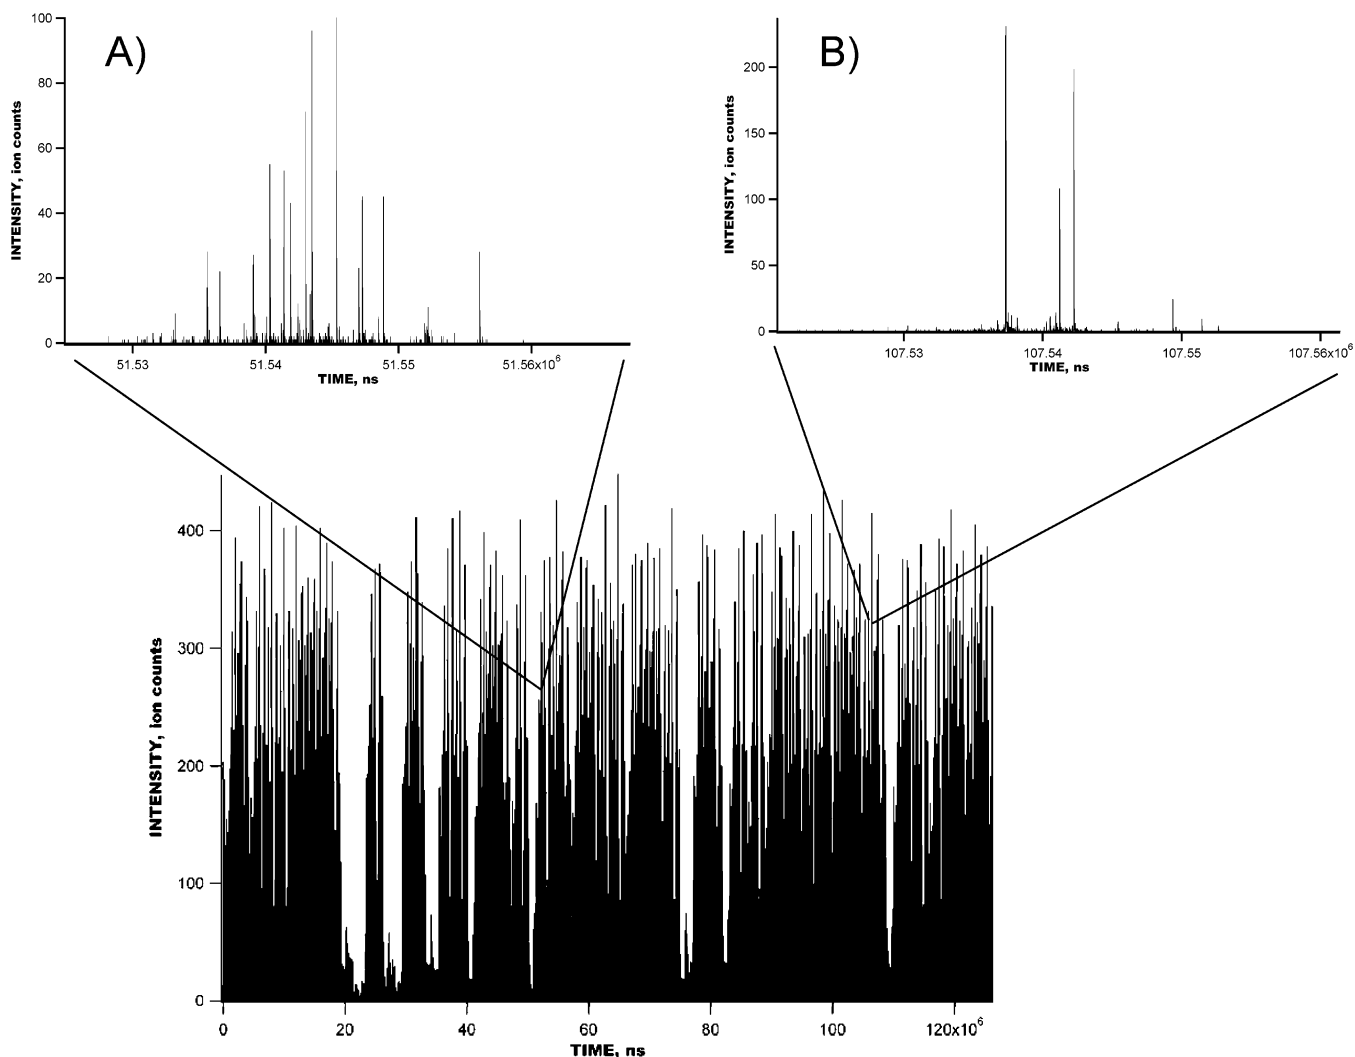

Figure 7. Experimental raw data signal acquired in the multiplexed IMS-TOF MS (Agilent) measurement with $1 \mu\text{M}$ solution of bradykinin, angiotensin I, fibrinopeptide, and neurotensin. Multiplexed IMS-TOF raw signal was acquired at 1.6-ns resolution and summed over 1000 IMS acquisitions, corresponding to 127 s. Multiplexed IMS separation encompasses 1270 TOF spectra. Insets A and B show small portions of the multiplexed IMS-TOF separation data stream, corresponding to single mass spectra.

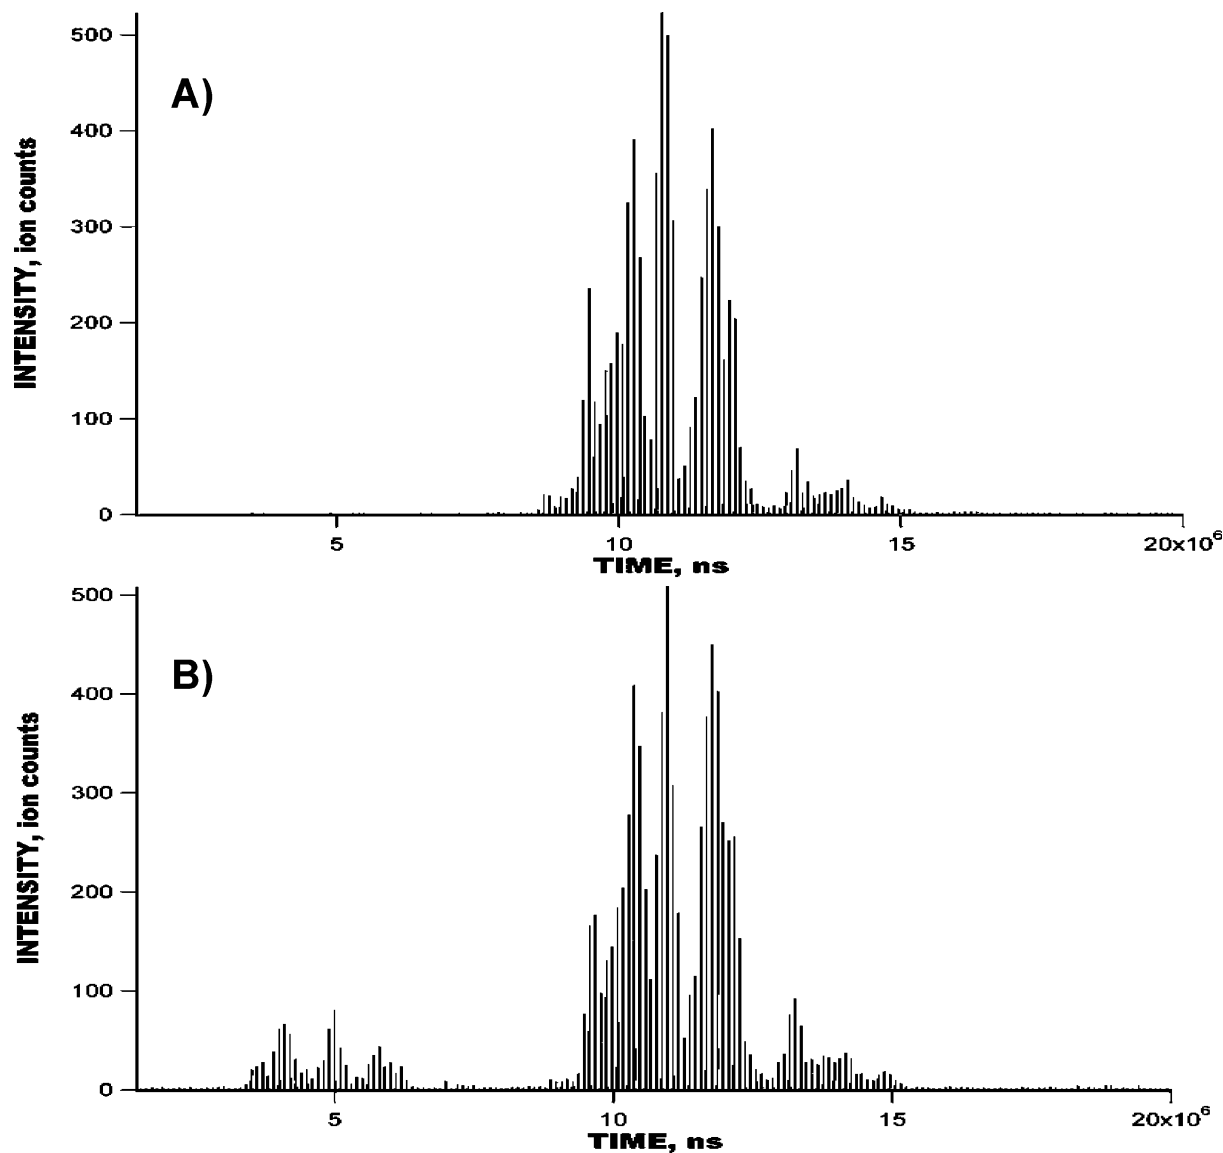

Figure 8. (A) Signal obtained with the peptide mixture in Figure 7 using IMS-TOF MS (Agilent) instrument operated in the signal averaging mode. Experimental conditions were identical to those used in Figure 7. (B) Reconstructed IMS-TOF signal from the multiplexed experiment in Figure 7. Each IMS separation in (A) and (B) comprises 1270 TOF mass spectra, and a total of 100 IMS separations were summed. The same SNR could be obtained ~60-fold faster than (A).

IMS-TOF (Q-Star) MS measurements (see Figures 5 and 6). Figure 8 shows a comparison of data acquired in the multiplexed and signal averaging modes. Figure 8A demonstrates the IMS-TOF (Agilent) signal acquired in the signal averaging mode, while Figure 8B shows the reconstructed signal obtained in the multiplexed experiment in Figure 7. Similar to Figure 5, both measurements used identical experimental conditions. The TOF spectrum and IMS spectrum acquisition rates were 100 μ s and 127 ms, respectively, and each data set represents a sum of 1000 IMS acquisitions. Signal reconstruction was performed with a single TOF bin resolution of 1.6 ns. A comparison between Figure 8A and B reveals that the drift times and IMS resolving power (separation peak width) for the reconstructed multiplexed IMS-TOF signal (Figure 8B) matches that of the signal averaging approach (Figure 8A). The IMS-TOF signal at drift times of ~5 ms was due to chemical noise variation and was not related to signal reconstruction algorithm. A detailed comparison of signal averaging and multiplexed data sets is shown in Figure 9, where small

portions of the TOF mass spectra, corresponding to the detected peptides from both the multiplexed and signal averaging experiments, are superimposed. Figure 9 is obtained by expanding short separation regions from Figure 8. Interestingly, reconstructed multiplexed spectra exhibited SNR improvements both for higher (e.g., bradykinin in Figure 9A) and lower abundance species (e.g., neurotensin in Figure 9C and fibrinopeptide in Figure 9D). For the signal averaging mode, the noise level corresponds to 3–4 ion counts; thus, a SNR of ~100 is obtained for the bradykinin signal in Figure 9A (Figure 9A, dashed line). The corresponding noise level for the multiplexed measurement was ~0.4–0.5 (Figure 9A, solid line), resulting in ~8-fold greater SNR for the same peptide. The noise levels from both multiplexed and signal averaging experiments are shown in the Figure 9A inset. An increase in the SNR for lower abundance species (Figure 9C, D) is evident in the isotopic distributions detected in the multiplexed versus signal averaging experiments. Data obtained in the signal averaging mode show distorted distribution of isotopic peaks,

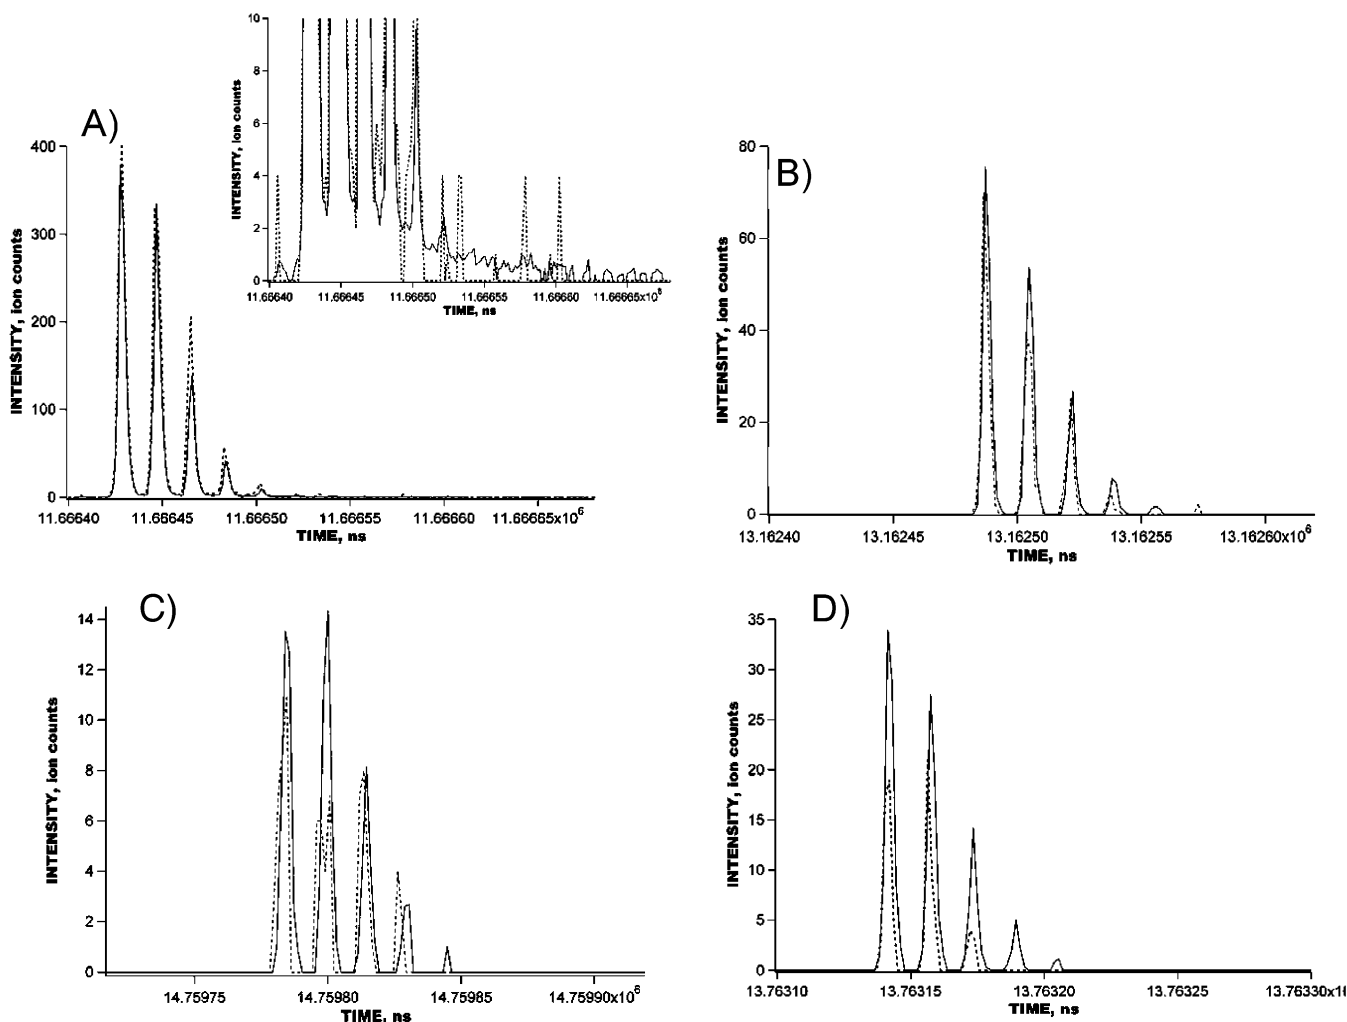

Figure 9. Superimposed portions of the IMS-TOF MS separations performed in the multiplexed (solid line) and signal averaging modes (dashed line) in Figure 8. The IMS-TOF MS (Agilent) instrument was operated under the conditions described in Figure 7. (A) A portion of one out of several TOF mass spectra corresponding to bradykinin signal; the inset shows noise levels for both signal averaging and multiplexed modes; (B) angiotensin I signal; (C) neurotensin signal; and (D) fibrinopeptide signal.

missing isotopic peaks, and noisy line shapes due to limitation in ion statistics.

An important characteristic that distinguishes the current approach from the earlier implementations of the HT-IMS^{27,28} is the combination of ion accumulation with multiplexing. In the ideal scenario, the ion trapping efficiency would remain constant for accumulation times extending to >10 ms. Given a 1-ms-long modulation bin comprising 10 submodulation bins (as in the current approach) and a gate opening time of 100 μ s, an average weighed accumulation time for a 7-bit sequence would be ~ 2 ms, resulting in a ~ 20 -fold (2 ms/100 μ s) increase in the ion cloud charge density. Therefore, an expected SNR increase, SNR_{mult}, would be

$$\text{SNR}_{\text{mult}} \approx \text{efficiency}_{\text{trap}} \times \text{gain}_{\text{mult}} = 20 \times 5.6 \approx 100 \quad (13)$$

$$\text{gain}_{\text{mult}} \approx \frac{\sqrt{2^N - 1}}{2} \quad (14)$$

where $\text{efficiency}_{\text{trap}}$ is the charge density increase due to ion

accumulation as compared to that of the continuous beam, $\text{gain}_{\text{mult}}$ is the multiplexing gain, and N is the number of PRS bits. If HT-IMS is operated at higher modulation rate based on, for example, a 10-bit sequence, an SNR increase would be limited to a multiplexing gain of ~ 16 . The drawback of running the instrument at higher modulation rate would be an increase in mathematical pseudonoise due to diffusion-driven ion cloud overlap and the loss of multiplexing advantage.

In measurements using a 1 μ M solution of reserpine, a charge collector positioned immediately downstream of the hourglass ion funnel gave rise to an ion current of ~ 50 pA. This current translates to the maximum of $\sim 3 \times 10^5$ singly charged ions that could be accumulated in the ion funnel trap in 1 ms. Figure 3B shows that charge density per ion packet does not increase with an increase in ion accumulation times longer than ~ 2 ms. Therefore, the charge capacity of the ion funnel trap under current experimental conditions was limited to $\sim 10^6$ ions. Based on the balance of Coulombic repulsion and effective potential forces, the theoretical charge capacity of the present ion funnel trap has earlier been estimated as $> 10^7$ elementary charges,³⁶ exceeding the present experimental situation by more than 1 order of

magnitude. An increase in the ion funnel effective potential due to an increase in the rf frequency and amplitude can potentially bridge this gap between theory and experiment. Based upon eq 13, the accumulation of greater ion populations (e.g., by extending the linear dynamic range of our ion funnel trap to enable a linear increase in ion populations at accumulation times up to ~ 10 ms) could potentially result in a further SNR improvement as compared to that experimentally achieved and an increase in the duty cycle to $\sim 95\%$ for ion utilization.

The experimental observation of an SNR increase greater than the multiplexing gain (see Figures 6 and 9) needs further explanation. Since both conventional and multiplexed IMS-TOF measurements were performed using the ion trapping mode, and there was no increase in the ion packet charge density for accumulation times greater than 2 ms (see Figure 3B), we infer that the SNR improvement is due to the multiplexing gain. This would be the case for one-dimensional multiplexed IMS separations, where the experimental gain could never exceed the theoretical multiplexing gain. However, in two-dimensional separations, an overlap of the ion clouds in TOF extraction region due to thermal diffusion (see raw multiplexed data in Figure 4B) increases the number of ions to be pulsed to the mass spectrometer in a single scan as compared to that of the standard IMS separation. This is also confirmed in modeled data (see Figure 2A), so that peak intensities of ~ 300 ions were observed with only 100 ions introduced per packet into the IMS drift tube. The inset B in Figure 4 and comparison of signal intensities in Figure 4 and Figure 5A consistently show that even before signal reconstruction ion intensities in the multiplexed IMS-TOF experiment exceed the signal maximum obtained in the signal averaging experiment. In these measurements, both the number of TOF packets with ions and the number of ions per TOF packet are increased, resulting in a SNR increase greater than the multiplexing gain. Thus, we would argue that a significant part of the multiplexing gain with IMS-TOF measurements arises from a second separation dimension (i.e., the MS). More rigorous validation of the SNR improvement due to ion packet overlap in the TOF extraction region is achievable via reducing the number of bits in the encoding sequence, which would enable further spatial separation of the ion packets. Such an investigation, however, is beyond the scope of this work.

Finally, a multiplexed IMS-TOF resolution in the IMS dimension (~ 70 for the IMS-Q-Star and ~ 45 for the IMS-Agilent TOF MS) was found to be similar to that for the conventional IMS-TOF (see Figures 5 and 8), implying a weak dependence of ion drift times on the space charge in the multiplexing experiments. Unlike atmospheric pressure HT-IMS, where IMS resolution is

primarily dependent on the gate opening time, in a lower pressure (~ 4 Torr) IMS separation, a separation peak width (~ 1 ms fwhm for the IMS-QStar TOF MS platform) is primarily determined by thermal diffusion (see eq 3). Further increases in the pressure and electric field strength are projected to facilitate an increase in the multiplexed IMS resolution, since the thermal diffusion term will be reduced while the gate opening time would remain constant (see Figure 3).

CONCLUSIONS

A newly developed multiplexed IMS-TOF MS approach has been modeled and experimentally implemented using an ESI source. We have found that previous results using Hadamard IMS have been limited by diffusion phenomena. Data reconstructed in the multiplexed IMS-TOF MS experiments using the new approach, and proper selection of the encoding sequence, showed a ~ 10 -fold increase in SNR can be obtained compared to the same instrument operating in the conventional signal averaging mode for a mixture of peptides. Further sensitivity improvements should be attainable by increasing the charge capacity of the ion accumulation trap and the efficiency of ion ejection from the trap with shorter gate pulses. Such an implementation could drastically minimize ion losses in the ESI-IMS interface, potentially providing $>95\%$ ion utilization efficiency. Since a multiplexed IMS-TOF MS separation can be obtained on a time scale of ~ 100 ms, the potential basis exists for a extremely high-throughput and sensitive platform, e.g., proteomics and system biology applications. Integration of the multiplexed IMS-TOF MS platform with on-line RPLC fractionation would potentially enable complete sample analysis involving 3D separations having substantially increased throughput compared to LC-MS, making such an approach highly attractive for many clinical applications.
