Central Division of Analytical Chemistry, Research Centre Jülich, 52425 Jülich, Germany, Laboratory of Analytical Chemistry, Department of Chemistry, University of Konstanz, 78457 Konstanz, Germany, and Laboratory of Neuromorphology, Department of Anatomy, Semmelweis University, Budapest, Hungary

Human brain proteins containing phosphorus, copper, and zinc were detected directly in protein spots in gels of a human brain sample after separation by two-dimensional gel electrophoresis using laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS). A powerful laser ablation system with cooled laser ablation chamber was coupled to a double-focusing sector field ICPMS. The separated protein spots in 2D gels were fast screened using the optimized microanalytical LA-ICPMS technique measured at medium mass resolution with a focused laser beam (wavelength, 213 nm; diameter of laser crater, 50 μm ; and laser power density, $3 \times 10^9 \text{ W cm}^{-2}$) with respect to selected three essential elements. Of 176 protein spots in 2D gel from a human brain sample, phosphorus, copper, and zinc were detected in 31, 43, and 49 protein spots, respectively. For the first time, uranium as a naturally occurring radioactive element was found in 20 selected protein spots. The detection limits for P, S, Cu, Zn and U were determined in singular protein spots with 0.0013, 1.29, 0.029, 0.063, and 0.000 01 mg g^{-1} , respectively. A combination of LA-ICPMS with matrix-assisted laser desorption/ionization Fourier transform ion cyclotron resonance mass spectrometry (MALDI-FTICR-MS) was applied for the identification of selected protein spots from human brain protein separated by 2D gel electrophoresis. Combining MALDI-FTICR-MS for the structure analysis of metal- and phosphorus-containing human brain proteins with LA-ICPMS, the direct analysis of heteroelements on separated proteins in 2D gels can be performed. For quantification of analytical LA-ICPMS data, the number of sulfur atoms per protein (and following the sulfur concentration) determined by MALDI-FTICR-MS was used for internal standardization. From the known sulfur concentration in protein, the concentration of other heteroelements was calculated. In addition, the number of phosphorylation and the phosphorylation sites of phosphorylated proteins

in the human brain sample detected by LA-ICPMS were determined by MALDI-FTICR-MS. This technique allows the study of posttranslational modifications in human brain proteins.

Proteins containing heteroatoms, such as phosphorylated proteins (phosphoproteins) and metal-containing proteins, play an important and essential role as cofactors in biological systems (e.g., in single cells or cell organelles) and are gaining increasing attention in the field of proteomics.^{1–4} Whereas the absence or deficiency of essential metals or metalloids (such as Fe, Cu, Se, Zn) in proteins results in deficiency diseases, these essential elements can also catalyze cytotoxic reactions.⁵ For example, reversible protein phosphorylation is a key determinant in many fundamental cellular functions, such as survival, differentiation, structural organization, and stress responses, and is relevant for many pathophysiological processes in carcinogenesis or neurodegenerative diseases (e.g., in Alzheimer's⁶ or Parkinson's disease^{7,8}). In addition, trace amounts of metals exist in Alzheimer's brain samples.^{9,10} Therefore, the characterization of phosphorus and metal-containing proteins which requires the analysis of phosphorus and metals and the identification of individual proteins is of increasing interest.^{9,11–17} For this challenging task in the

proteomics area (phosphoproteomics and analysis of metal-containing proteins, respectively), sensitive and powerful analytical techniques combining inorganic and organic mass spectrometry are required. The quantitative determination of phosphorus and metal concentrations in separated protein spots in gels after two-dimensional (2D) gel electrophoresis of proteins was performed, for example, by inductively coupled plasma mass spectrometry (ICPMS) after excision of the protein spot from the gel and digestion.¹⁵ Using ICPMS in combination with ESI-FTICR-MS, electrospray ionization Fourier transform ion cyclotron resonance mass spectrometry, the number of phosphorylations in Tau protein, a target protein in Alzheimer's disease, was determined from normal human brain to be 17.¹³ Disadvantages of the use of ICPMS as an atomic mass spectrometric technique are the more time-consuming excision and digestion of all separated protein spots and a great danger of possible contamination during sample preparation steps. Therefore, the method of choice is the use of laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS) for fast detection of proteins containing phosphorus and metal ions. For this purpose, LA-ICPMS was applied for the microlocal element analysis of separated protein spots in gels after two-dimensional (2D) gel electrophoresis.^{9,13,14} This powerful screening method for the detection of separated phosphoproteins and metal-containing proteins, (e.g., Fe, Zn, Cu), directly in 2D gels by LA-ICPMS was developed for studying posttranslational modifications in proteins of mitochondria.¹⁴ For quantification of analytical data, sulfur was used as the internal standard element because the sulfur concentration can be derived from the number of cystein residues in the protein investigated as a result of mass spectrometric investigations by MALDI-FTICR-MS.¹⁴ In addition, quantification of the analytical data from direct microlocal element analysis by LA-ICPMS, and new calibration strategies via 1D calibration gels or by solution-based calibration strategy in LA-ICPMS were proposed.^{13,14}

For the analysis of phosphorus and metals in 2D gels by LA-ICPMS, a cooled laser ablation chamber (using two Peltier elements in serial connection under the target holder made of aluminum) was applied, which results in an improvement of accuracy and precision of analytical data.¹⁸ Using this experimental arrangement, tracer experiments by means of isotopic-enriched tracers (⁵⁴Fe, ⁶⁵Cu, and ⁶⁷Zn) doped to two-dimensional gels of separated Alzheimer's diseased brain proteins after 2D gel electrophoresis to study the formation of proteins containing Cu, Zn and Fe in a human brain sample were carried out.¹⁹ In these tracer experiments, the protein spots were investigated systematically by LA-ICPMS with respect to ⁵⁴Fe/⁵⁶Fe, ⁶⁵Cu/⁶³Cu, and ⁶⁷Zn/⁶⁴Zn isotope ratios.¹⁹ By isotope

ratio measurements using LA-ICPMS, we found metal-containing proteins with natural isotope composition and enriched isotope ratios. Those protein spots with a natural isotope composition of Cu, Zn, or Fe are stable enough to survive the reducing conditions during gel electrophoresis. On the other hand, proteins with a changed isotope ratio of metals (isotope enrichments) studied in comparison to the isotope ratio in nature demonstrate the accumulation of enriched spikes on metal-containing protein complexes during the tracer experiments in 2D gels.¹⁹

To solve the most important inherent problem in LA-ICPMS, that is, the appearance of isobaric interferences (e.g., the determination of phosphorus, copper, and zinc is disturbed by the formation of molecular ions such as ¹⁵N¹⁶O⁺, ¹⁴N¹⁷O⁺, and ¹⁴N¹⁶O¹H⁺ at ³¹P⁺; ¹⁶O₂⁺ at ³²S⁺; ⁴⁰Ar¹⁶O⁺ at ⁵⁶Fe⁺; ⁴⁰Ar²³Na⁺ at ⁶³Cu⁺; ⁴⁰Ar²⁵Mg⁺ at ⁶⁵Cu⁺; and ³²S₂⁺ at ⁶⁴Zn⁺, respectively), a double-focusing sector field mass spectrometer with an inductively coupled plasma ion source at medium mass resolution ($m/\Delta m \sim 4400$) was applied for the separation of isobaric interferences of molecular ions from analyte ions in small amounts of protein samples.^{13,14}

In addition, to determine the phosphorus and metal concentrations by element analytical method using LA-ICPMS, the identification and structure analysis of the investigated proteins, including the determination of the sequence of amino acids, are necessary by organic mass spectrometry, including the analysis of posttranslational modifications such as glycosylation, fatty acylation, and phosphorylation. For protein identification, organic mass spectrometry methods that employ soft ionization techniques (matrix-assisted laser desorption/ionization, MALDI, or electrospray ionization, ESI) permit the identification of large biomolecules, such as proteins, after the excision and tryptic digestion of the protein spot from a 2D gel.^{11,20,21} Subsequent analysis of the derived peptide mixture by organic mass spectrometry yields results on the posttranslational modifications of proteins, for example, phosphorylation or the formation of metal-bonding proteins.^{9,22–24} Although MALDI and ESI mass spectrometry can be used for the identification of phosphorylation sites in proteins, these techniques cannot provide direct quantitative determinations of phosphorus and metals in biological samples; therefore, a combination with atomic mass spectrometry is required.

The aim of this work is to identify phosphorus- and metal-containing proteins and to analyze the phosphorylation of proteins in a complex protein mixture in human brain samples (somatomotor cortex). Therefore, a fast, direct screening technique with a lateral resolution in the 10–50 μm range was applied for the quasimultaneous multielement determination of phosphorus and metal content in small protein spots in two-dimensional gels by LA-ICPMS. In addition to copper and zinc as essential elements, uranium as an example of a nonessential naturally occurring toxic and radioactive element will be measured. The combination of

Figure 1. Two-dimensional gel after electrophoretic separation of proteins from human brain sample (somatomotor cortex) using an IPG strip 4–7 for the first dimension and an SDS–PAGE for the second dimension; 176 separated protein spots were analyzed.

LA-ICPMS with high-resolution MALDI-FTICR-MS will be used as a suitable tool for protein identification and quantification of protein phosphorylation as well as of metal concentrations.

EXPERIMENTAL SECTION

LA-ICPMS Instrumentation. A double-focusing sector field ICPMS (ELEMENT, Thermo Electron, Bremen, Germany) coupled to a powerful Nd:YAG laser ablation system Ablascop (Bioptric, Berlin) operating at wavelength, 213 nm; diameter of laser crater, 50 μm ; and laser power density, $3 \times 10^9 \text{ W cm}^{-2}$ was used for the microlocal analysis of phosphorus, metals, and sulfur in protein spots in 2D gel. The laser beam was focused on separated protein spots, the ablated material was transported by argon as a carrier gas into the inductively coupled plasma (ICP). The ICP torch was shielded with a grounded platinum electrode (GuardElectrode, Thermo Electron, Bremen). For optimization of experimental parameters, an ultrasonic nebulizer (USN, CETAC Technologies Inc., Omaha, NB) was used, which was coupled on-line to the laser ablation chamber. The ions formed in the ICP were extracted in the sector-field mass spectrometer and separated according to their mass-to-charge ratios. To separate possible interfering molecular ions from the atomic ions $^{31}\text{P}^+$, $^{32}\text{S}^+$, $^{63}\text{Cu}^+$, and $^{64}\text{Zn}^+$, all LA-ICPMS measurements were performed at medium mass resolution ($m/\Delta m$ of 4400). In addition, uranium was analyzed simultaneously at medium mass resolution by LA-ICPMS, even though no interferences occur at mass 238 u, because only a small amount of protein is available in separated spots, and therefore, a second measurement at low mass resolution is not possible. The optimized experimental parameters of the LA-ICPMS measurements are summarized in Table 1.

Table 1. Optimized Experimental Parameters of LA-ICPMS

ICPMS		
rf power		1200
cooling gas flow rate		18 L min ⁻¹
auxiliary gas flow rate		1 L min ⁻¹
nebulizer (carrier) gas flow rate		1.2 L min ⁻¹
mass resolution ($m/\Delta m$)		4400
no. of runs (pass)		150 (1)
analysis time per spot		90 s
Laser Ablation		
laser ablation system		Ablascop
wavelength		213 nm
laser power density		$3 \times 10^9 \text{ W cm}^{-2}$
laser energy per pulse		6 mJ
repetition frequency		20 Hz
spot diameter		50 μm

LA-ICPMS Measurements and Quantification Procedure.

The separated protein spots in the 2D gels (Figure 1) were screened using LA-ICPMS at mass-to-charge ratios of 31, 32, 63, 64, and 238 with respect to the measurement of P^+ , S^+ , Cu^+ , Zn^+ , and U^+ ion intensities. Several protein spots containing P, S, Cu, Zn, and U were selected for further analytical studies on an additional 2D gel. The quantification procedure was performed by measuring ion intensities of analytes in the protein spots, as described in a previous paper.¹⁴ The element concentration in the protein spots was determined with respect to the known sulfur concentration (if sulfur-containing protein was identified by MALDI-FTICR-MS). For quantification of analytical LA-ICPMS data, the number of cystein residues and following the number

of sulfur atoms per protein were measured by MALDI-FTICR-MS. By this means sulfur as internal standard element was used. From the known sulfur concentration in the protein, the concentration of other heteroelements was calculated, as described in a previous paper.¹⁴

The concentrations of these elements in the blank gel marked in Figure 1 were determined after microwave digestion via measurement of the background intensity of $^{31}\text{P}^+$, $^{32}\text{S}^+$, $^{63}\text{Cu}^+$, $^{64}\text{Zn}^+$, and $^{238}\text{U}^+$ by external calibration using ICPMS.

MALDI-FTICR-MS Instrumentation and Measurements.

MALDI-FTICR-MS measurements on protein samples after separation by 2D gel electrophoresis and subsequent tryptic in-gel digestion were performed with a Bruker Apex II FTICR instrument equipped with an actively shielded 7-T superconducting magnet, a cylindrical infinity ICR analyzer cell, and an external MALDI ion source. A detailed description of this instrumentation has been given elsewhere.^{19,20} The MALDI source with pulsed nitrogen laser is operated at 337 nm, and ions are directly desorbed into a hexapole ion guide while being cooled during formation using Ar as the collision gas. Ions generated by 20 laser shots were accumulated in the hexapole at 15 V and extracted at 7 V into the analyzer cell. A 100 mg/mL solution of 2,5-dihydroxybenzoic acid (DHB, Aldrich, Germany) in acetonitrile/0.1% trifluoroacetic acid in water (2:1) was used as the matrix. A volume of 0.5 μL of matrix solution and 0.5 μL of sample solution was mixed on the stainless steel MALDI sample target and allowed to dry.

Samples and Sample Preparation. The isolated proteins from a human brain sample (somatomotor cortex) were analyzed directly with respect to phosphorus, sulfur, copper, zinc, and uranium content by LA-ICPMS after 2D gel electrophoresis. Proteins were digested with trypsin (Progenia, Mannheim, Germany) and analyzed by MALDI-FTICR-MS as previously described.¹⁴

Standards and Reagents. Concentrated nitric acid of supra grade purity from Merck (Darmstadt, Germany) was used for sample digestion of gel blank. Phosphorus, sulfur, copper, zinc, and uranium standard stock solutions for the calibration procedures were obtained from Merck (Darmstadt, Germany) and from the National Institute of Standards and Technology (NIST, Gaithersburg, MD). For all dilutions, deionized Milli-Q water (18 M Ω) was obtained from a Millipore (Millipore Bedford, MA) Milli-Q-Plus water purifier.

Protein Separation by Two-Dimensional Gel Electrophoresis. To isolate the soluble and membrane proteins from human brain samples, a piece of somatomotor cortex was taken, and a buffer, containing NaCl, Tris-HCl buffer (Merck, Darmstadt, Germany), and protease inhibitors (e.g. aprotinin, antipain, leupeptin, pepstatin, from Sigma, Deisenhofen, Germany) was added, and the mixture was ultracentrifuged. The pellet was resuspended in the buffer, which also included Triton X-100 (Sigma, Deisenhofen, Germany), shaken, and centrifuged. The proteins in the resuspended pellet were concentrated by acetone precipitation.

The isolated brain proteins from human brain dissolved in rehydration buffer (8 M Harnstoff, 2% (w/v) CHAPS, 2% (v/v) Pharmalyt 4-7 (SERVA Electrophoresis GmbH, Heidelberg, Germany), 15 mM DTT) were rehydrated overnight on IPG strips 4-7 (BioRad, Muenchen, Germany). In the first step, the proteins

were separated by isoelectric focusing, separating the proteins according to their isoelectric point in the Multiphor II instrument (Amersham Bioscience Europe GmbH, Germany). Separation of the complex constituents was performed by a second dimension (SDS-PAGE) to separate the proteins according to their molecular weight in a polyacrylamide gel, 20 cm \times 20 cm, described by Laemmli.²⁵ A molecular weight marker (Merck, Darmstadt, Germany) with a mass range from 14.2 to 67 kDa was used during the second dimension of the gel electrophoresis.

Proteins were stained by the silver staining technique described by Heukeshoven and Dernick²⁶ using silver nitrate and calcium carbonate together with formaldehyde (Merck, Darmstadt, Germany) for LA-ICPMS and for MALDI-FTICR-MS. All protein separations were performed in duplicate by using the selected separated proteins in parallel from one gel for analysis of P, S, Cu, Zn, and U directly by LA-ICPMS and the second gel for identification of proteins by MALDI-FTICR-MS. Phosphorus and metal-containing protein spots selected by LA-ICPMS were cut out and digested with trypsin (Progenia, Mannheim, Germany) and analyzed with MALDI-FTICR-MS as described previously.¹⁴

RESULTS AND DISCUSSION

Separation of Human Proteins. Human protein complexes were separated by two-dimensional gel electrophoresis as described in the Experimental Section. 2D gels were stained by the silver staining technique. In Figure 1, a two-dimensional gel is shown after the separation of proteins from a human brain sample (somatomotor cortex) by 2D gel electrophoresis. The P and metal contents in proteins with a molecular weight were determined mass spectrometrically.

Screening of Protein Spots in Two-Dimensional Gels by LA-ICPMS. Separated protein spots were subjected to a systematic screen for various elements using an analytical screening technique by means of LA-ICPMS.¹⁴ A total of 176 well-separated protein spots in 14 selected parts (cut out) marked in Figure 1 were analyzed by LA-ICPMS with respect to five selected analytes, including S for internal standardization. In most of the protein spots (e.g., in spot numbers 1a-d, 1f, 1j, 2a-c, 3c, 4f, 5b, 6a, 6b, 6e, 6f, 7a-c, 8e, 8f, 8-l, 9-l, 10a-d, 12b, 13a, 13b, 14a, and 14b) none of the elements of interest (P, Cu, Zn, and U) was found. If phosphorus was measured in individual protein spots, Cu and Zn were also often found by LA-ICPMS at higher ion intensities in comparison to phosphorus. In several proteins, only selected elements were present (e.g., P in 10e and 10f; Cu in 1j; Zn in 3c; P and Zn in 3f; Zn in 12c; U in 10a), or the ion intensities of $^{31}\text{P}^+$, $^{64}\text{Zn}^+$, $^{63}\text{Cu}^+$, or $^{238}\text{U}^+$ were relatively low (near the background signal). In some protein spots (e.g., Cu and Zn in 2l and 9d; P in 9b; P, Cu, Zn, and U in 12a), and in some, high ion intensities of the analytes were measured. We attempted to use MALDI-FTICR-MS to identify phosphorylated protein spots containing metals detected by LA-ICPMS. From 176 spots studied in 2D gel, 31 proteins containing phosphorus were found; 43 proteins contained Cu; and in 49 protein spots, Zn was measured, some at high ion intensities (e.g., in spots 2g, 2l, 5a, 9b, 9d, 10j, 12a, and 14c). In 20 protein spots, uranium was detected. The highest $^{238}\text{U}^+$ ion intensity of ~ 4000 cps was measured in protein spot 11e (see

(25) Laemmli, U. K. *Nature* **1970**, 277, 680.

(26) Heukeshoven, J.; Dernick, R. *Electrophoresis* **1985**, 6, 103.

Figure 2. Transient signals of $^{31}\text{P}^+$ measured in separated protein spots of human brain sample in cuts 3 and 5 measured by sector field LA-ICPMS at mass resolution $m/\Delta m = 4400$.

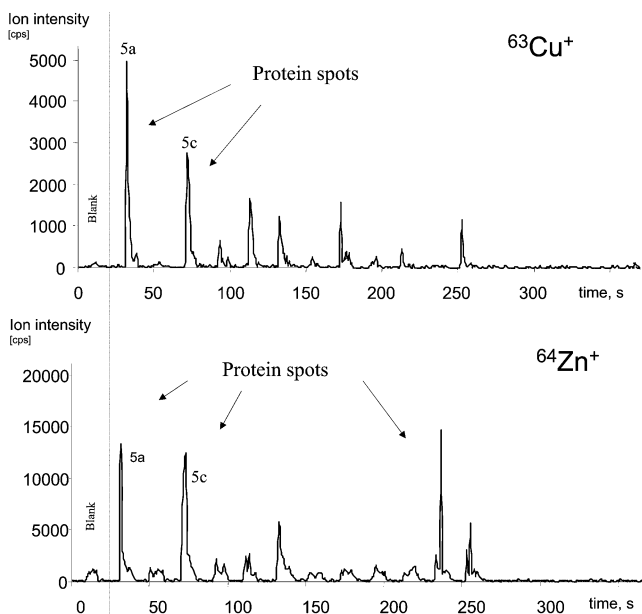

Figure 3. Transient signals for $^{63}\text{Cu}^+$ and $^{64}\text{Zn}^+$ in protein spots of human brain sample (cut 5) separated by 2-dimensional gel electrophoresis measured by sector field LA-ICPMS.

Figure 6), followed by spot 6g with 2200 cps. This finding also correlates with the occurrence of $^{31}\text{P}^+$, $^{63}\text{Cu}^+$, and $^{64}\text{Zn}^+$ ion intensities in both protein spots. It is interesting to note that only in protein spot 10a does uranium appear alone with a $^{238}\text{U}^+$ ion intensity of 300 cps (the background signal was <1 cps).

An advantage of LA-ICPMS is that the screening of separated protein spots in a two-dimensional gel and the qualitative measurements of a multitude of protein spots was performed in just a few hours. This main feature of the screening procedure developed using LA-ICPMS can help to significantly reduce the time required for structure analysis by a preselection of protein spots containing P, S, and several metals of interest. Table 2

summarizes the results of the qualitative LA-ICPMS analysis of 18 selected protein spots in 2D gels containing P, Cu, Zn, and U or some of these elements. After a qualitative survey analysis using LA-ICPMS, several protein spots from human brain sample containing P, Cu, Zn, and U can be analyzed by MALDI-FTICR-MS with high mass accuracy and mass resolution. But the denaturing and reducing conditions (denaturing agent, sodium dodecyl sulfate, SDS) during the separation of proteins in the second dimension partly releases the naturally bound metal ions. Recently, it was demonstrated in tracer experiments that stable metal-protein complexes can survive denaturing and reducing conditions.¹⁹ Furthermore, in this work, it was shown that certain proteins can accumulate metal ions during the tracer experiments (e.g., new Zn- and Fe-containing proteins were detected).¹⁹ The detection of metals at low concentration range in a protein spot by LA-ICPMS also indicates the ability of the protein to bind metal ions during washing steps with contaminants or, for example, during silver staining.¹⁴ In contrast, the phosphorus is covalently bound to the protein and will not be removed by the electrophoretic procedure. To avoid dephosphorylation of the proteins by phosphatases, a mixture of phosphatase inhibitors was added throughout the isolation and the lysis of human brain sample.

Transient signals of $^{31}\text{P}^+$, $^{63}\text{Cu}^+$, $^{64}\text{Zn}^+$, and $^{238}\text{U}^+$ in several cuts of 2D gel measured by LA-ICPMS are demonstrated in Figures 2–7. Figure 2 shows transient signals for the detection of phosphorylated proteins for cuts 3 and 5. The transient signals of $^{31}\text{P}^+$ in selected protein spots in the cut of 2D gel are shown as a function of measuring time using LA-ICPMS. Due to relatively high background intensity at mass 31 u in these measurements (of about 200–400 cps), it is sometimes difficult to detect phosphorus in protein spots. The highest $^{31}\text{P}^+$ ion intensity from these cuts was observed in protein spots 3n and 5a. Mostly higher ion intensities at lower background were observed for $^{63}\text{Cu}^+$ and $^{64}\text{Zn}^+$, in comparison to $^{31}\text{P}^+$ in the investigated phosphoproteins, as demonstrated for cut 5 (e.g., in proteins 5a and 5c) of 2D gel of human brain sample. In Figure 3, transient signals of $^{63}\text{Cu}^+$ and $^{64}\text{Zn}^+$ were measured by LA-ICPMS in several protein spots of cut 5. In protein spot 5a, all analytes of interest were detected. In addition, $^{238}\text{U}^+$ with, in general, lower ion intensity was found in individual protein spots (3b, 3f, 3k, and 5a), whereby the background signal at mass 238 u was the lowest of all analytes studied. In cut 2, only in one protein spot (2g) were P, Cu, and Zn with remarkable ion intensities detected simultaneously (see Figure 4). Other protein spots contained only Cu and Zn (2l and 2m). No significant uranium ion intensities were measured in any proteins (cut 2); however, $^{238}\text{U}^+$ with ion intensities of several hundred cps (counts per second) was measured in spots 9b and 9e (see Figure 5). The occurrence of uranium in protein spot 9b correlates with a high $^{31}\text{P}^+$ intensity. In protein spot 9d, significantly lower $^{31}\text{P}^+$ intensity was measured, but high $^{63}\text{Cu}^+$ and $^{64}\text{Zn}^+$ intensities were also found. In Figure 6, transient signals of $^{31}\text{P}^+$, $^{63}\text{Cu}^+$, $^{64}\text{Zn}^+$, and $^{238}\text{U}^+$ are summarized, and only in spot 11e were all elements measured simultaneously with relatively high ion intensities. Protein spots 11a and 11d contained P and Cu, as well as Zn. Figure 7 shows transient signals for cut 13. In the phosphoproteins (spots 13l and 13c), $^{63}\text{Cu}^+$, $^{64}\text{Zn}^+$ and $^{238}\text{U}^+$ were also detected by LA-ICPMS.

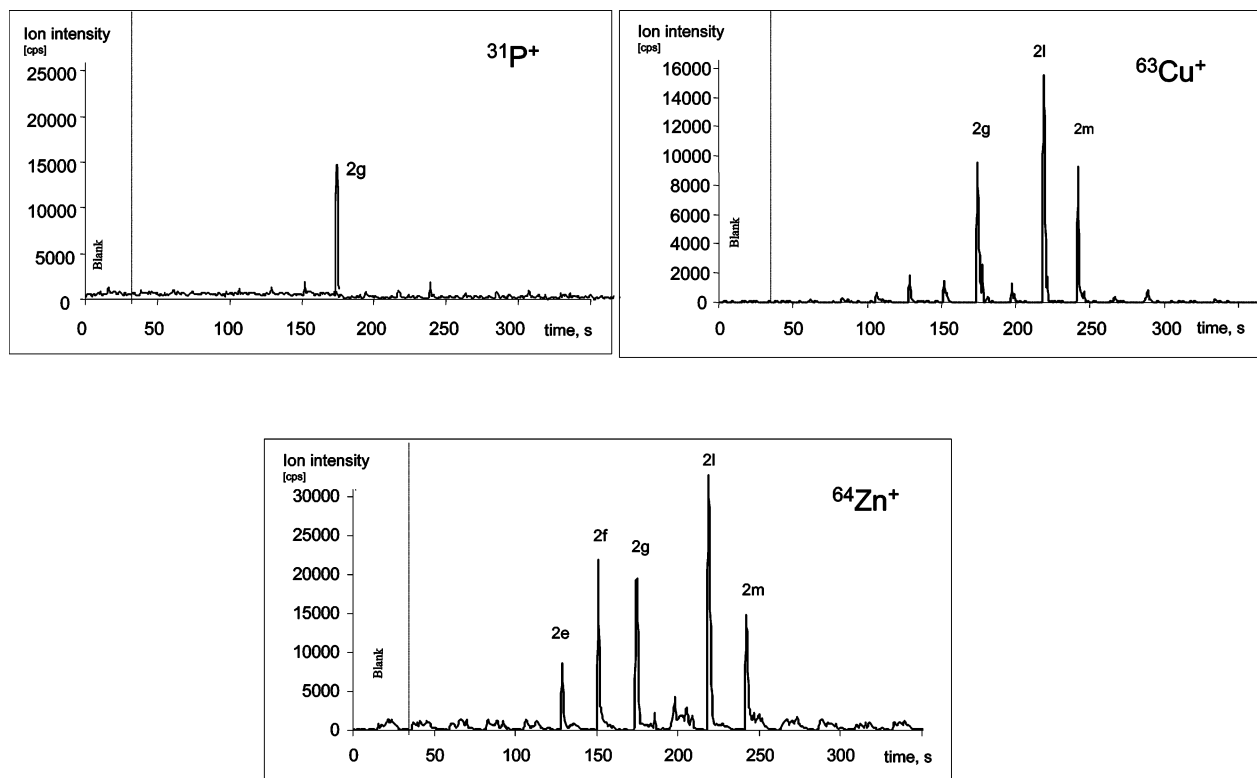

Figure 4. Transient signals for $^{31}\text{P}^+$, $^{63}\text{Cu}^+$, and $^{64}\text{Zn}^+$ in protein spots of human brain sample (cut 2) separated by 2-dimensional gel electrophoresis measured by sector field LA-ICPMS.

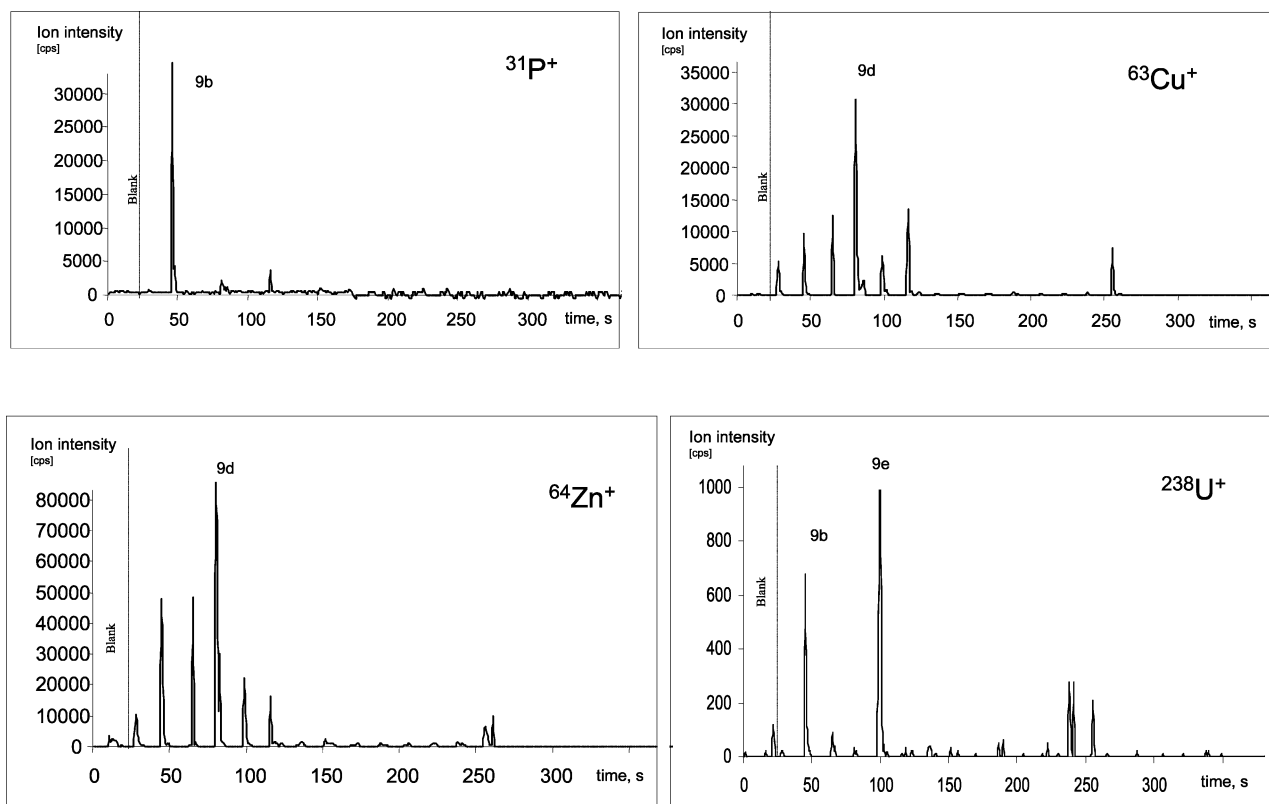

Figure 5. Transient signals for $^{31}\text{P}^+$, $^{63}\text{Cu}^+$, $^{64}\text{Zn}^+$, and $^{238}\text{U}^+$ in protein spots of human brain sample (cut 9) separated by 2-dimensional gel electrophoresis measured by sector field LA-ICPMS.

Identification of Proteins by High-Resolution MALDI-FTICR-MS. We attempted to identify individual protein spots from human brain separated by 2D gel electrophoresis by biopolymer

mass spectrometry using MALDI-FTICR-MS after excision from 2D gel and tryptic digestion. The methods for the identification and characterization of proteins by mass spectrometry generally

include the following analytical procedures: (i) degradation of the protein into small peptides by enzymatic treatment and (ii) differential peptide mapping using different databases.²⁷ The development of FTICR mass spectrometry has recently enabled a breakthrough in the high-resolution mass spectrometric structure analysis of proteins using MALDI ionization;^{9,19} in combination with 2D gel electrophoresis, the high (sub-parts-per-million) mass determination accuracy and isotopic fine structure by FTICR-MS provides particular advantages for the identification of proteins of medium and low abundance. The primary structure of selected proteins can be directly identified after tryptic digestion by MALDI-FTICR-MS and afterward a database search using, for

example, Mascot peptide mass fingerprint²⁸ for protein identification. Table 3 summarizes the results of the identification and quantification of sulfur of several proteins using MALDI-FTICR-MS. For example, spot 3n was identified as α -internexin (containing six cystein residues) with a molecular weight of 55.4 kDa. Spot 4n was identified as creatine kinase β -chain (containing 16 cystein residues) and 3f as vacuolar ATP synthase catalytic subunit A containing 29 cystein residues. The observed molecular weight of proteins in the analyzed protein in the 2D gel corresponds to the calculated value.

Determination of Concentrations and Element Ratios in Protein Spots in 2D Gel after Separation by Gel Electrophoresis Using LA-ICPMS. LA-ICPMS is a promising and fast surface analytical technique for the direct microlocal analysis of protein spots in a two-dimensional gel to demonstrate the occurrence of P, Cu, Zn, and other elements (such as U).

$^{31}\text{P}^+$ ion intensities were measured by LA-ICPMS, and the data were quantified in the protein spots identified by MALDI-FTICR-MS using sulfur as the internal standard element. For example, in protein spot 2l (tubulin β -4 chain) with a molecular weight of 50.4 kDa, the phosphorus concentration was determined by combination of organic and atomic mass spectrometry to be 0.12 mg g⁻¹. The phosphorylation state was determined in protein spot 2l to be 6. In Table 4, the results of quantification for P, Cu, and Zn on selected protein spot 2l and the detection limits measured in the gel blank (silver-stained) after digestion are given.

The problem in the evaluation of analytical data was the high background of sulfur due to contamination of 2D gel during the

spots are summarized in ratios in Table 5. All element ratios are < 1 .

Selected protein spots in 2D gel containing uranium were identified after tryptic digestion (e.g., α -internexin or vacuolar synthase ATP with molecular weights of 55.53 and 68.30 KDa, respectively). The mass spectrum of spot 3n (α -internexin) with the identified peptides is shown in Figure 8. The protein could be identified with a good high score of 213 from the mascot database (www.matrixscience.com). Three modified peptides containing, in part, P, Fe, Zn, and Cu could be identified. The phosphorylated peptide K⁴⁴⁸–K⁴⁶¹ (E⁴⁴⁹–K⁴⁶²) contains a phosphoserine at S⁴⁶⁰ or S⁴⁵⁶. In Figure 9, the mass spectrum of spot 4m (GFAP, glial fibrillary acidic protein) is shown. In this protein, no modifications could be found by using MALDI-FTICR-MS.

Additional isotope ratio measurements of uranium in U-containing protein spots showed, as expected, that all of them contained uranium of natural isotopic composition. To study

Figure 8. MALDI-FTICR mass spectrum of protein spot 3n (α -internexin) with the identified peptides and phosphopeptide K⁴⁴⁸–K⁴⁶¹ (E⁴⁴⁹–K⁴⁶²) using Mascot database²⁸ for peptide mass fingerprint for protein identification.

uranium-binding proteins, tracer experiments were performed using ²³⁵U-enriched uranium whereby the isotope tracer was doped to the brain sample before and after 2D gel electrophoresis. Protein spots with an increased ²³⁵U/²³⁸U isotope ratio were detected by LA-ICPMS in gels, for example, of Alzheimer-diseased brain samples doped with ²³⁵U-enriched uranium after 2D gel

electrophoresis.²⁴ This result demonstrates that certain proteins are able to accumulate uranium. The detection limit of LA-ICPMS for uranium in separated protein spots in 2D gels was found to be 10 ng g⁻¹.²⁹

Future work will be focused on development of isotope dilution analysis via on-line solution-based calibration in LA-ICPMS using

a micronebulizer inserted directly into the cooled laser ablation chamber.³⁰

CONCLUSION

In the present study, 176 well-separated protein spots in two-dimensional gels after 2D gel electrophoresis were screened with respect to the occurrence of P, Cu, Zn, and U by LA-ICPMS as a microlocal analytical technique with multielement capability. Phosphorus and metal-containing proteins were detected in short analysis times using LA-ICPMS with a cooled laser ablation chamber. The combination of high-resolution MALDI-FTICR-MS and LA-ICPMS represents a powerful tool for the identification of phosphorylated and metal-containing human brain proteins and determination of phosphorus and metal content in selected

proteins. The complementary data from the two methods are particularly valuable in the case of multiple modifications for which no other currently available technique will provide corresponding protein information. The most important problem for the determination of phosphorus and other elements in the gel is possible contamination during sample preparation or by staining. Future work will focus on improving the screening technique using a laser ablation system with better lateral resolution and development of further quantification procedures.

ACKNOWLEDGMENT
